

# Lecture 30 —Profiling and Scalability

Jeff Zarnett

`jzarnett@uwaterloo.ca`

Department of Electrical and Computer Engineering  
University of Waterloo

December 28, 2016

Following the discussion of profiling and our look into cloud computing, we should take some time to understand performance and scalability.

Recall that what we want in scalability is that we can take our software from 1 user to 100 to 10 million.

Finishing work faster helps, but it's not the only way.

To to scale up, we probably need to do some profiling to find out what's slow.

But we have some things we need to worry about when we want to get away from just working on our dev machines and into big numbers of users.

Scalability testing is very different from QA testing.

You will do development and QA on your local computer and all you really care about is whether the program produces the correct output “fast enough”.

That's fine, but it's no way to test if it scales.

You should be testing on the machines that are going to run the program in the live environment.

Low-end systems have very different limiting factors.

You might be limited by the 4GB of RAM in your laptop and that would go away in the 64GB of RAM server you're using.

So you might spend a great deal of time worrying about RAM usage when it turns out it doesn't matter.

Use a “real” workload, as much as one can possibly simulate.

Legal reasons might prevent you from using actual customer data, but you should be trying to use the best approximation of it that you have.

If you only generate some test data, you may not accurately represent the way the users are going to behave the system.

Your test set run summary reports occasionally... your users might run them every hour.

“More is the new more.”

It's okay to use lighter workloads for regression testing.

To see how your system performs under pressure, you actually need to put it under pressure.

You can simulate pressure by limiting RAM or running something very CPU-intensive concurrently, but it's just not the same.

These tests, incidentally, are of great interest to the customers, who would like to know that you can deliver.

# Reproducibility and Regression Testing

Science rule 1: results need to be reproducible!

Remember that good programming practice says that unit tests should be run, and re-run to make sure it all works.

Old (solved) performance issues are not nice to see either.

Or a new change that slows the whole program down is not a success either.

Let's do an example.

The application is deployed on two systems – one application server and one database server. The data is stored on an external SAN with RAID0 configuration.

A Java program ran to simulate object creation with 15 threads.

The performance metric is objects created per second.

# Scalability Fail(ability)

This is, to use the technical term, “not good”.

# Elementary, My Dear Watson!

*It is a capital mistake to theorize before one has data. Insensibly one begins to twist facts to suit theories, instead of theories to suit facts.*

- Sherlock Holmes (*A Scandal in Bohemia*; Sir Arthur Conan Doyle)

At a high level we probably have four potential culprits to start with:

- 1 CPU
- 2 Memory
- 3 Disk
- 4 Network

These are, obviously, more categories than specific causes.

CPU is probably the easiest of these to diagnose.

Something like `top` or Task Manager will tell you pretty quickly if the CPU is busy. You can look at the %CPU columns and see where all your CPU is going.

# Felicity Smoak, “Overwatch” (Oracle was taken)

Still, that tells you about right now; what about the long term average?

Checking with my machine “Loki”, that donates its free CPU cycles to world community grid (I’m singlehandedly saving the world, you see.):

```
top - 07:28:19 up 151 days, 23:38,  8 users,  load average: 0.87, 0.92, 0.91
```

Those last three numbers are the one, five, and fifteen minute averages of CPU load, respectively.

Lower numbers mean less CPU usage and a less busy machine.

Picture a single core of a CPU as a lane of traffic.

You are a bridge operator and so you need to monitor how many cars are waiting to cross that bridge.

If no cars are waiting, traffic is good and drivers are happy.

If there is a backup of cars, then there will be delays.

- 1 0.00 means no traffic (and in fact anything between 0.00 and 0.99) means we're under capacity and there will be no delay.
- 2 1.00 means we are exactly at capacity. Everything is okay, but if one more car shows up, there will be a delay.
- 3 Anything above 1.00 means there's a backup (delay). If we have 2.00 load, then the bridge is full and there's an equal number of cars waiting to get on the bridge.

= load of 1.00

= load of 0.50

= load of 1.70

Being at or above 1.00 isn't necessarily bad, but you should be concerned if there is consistent load of 1.00 or above.

And if you are below 1.00 but getting close to it, you know how much room you have to scale things up.

If load is above 0.70 then it's probably time to investigate. If it's at 1.00 consistently we have a serious problem.

If it's up to 5.00 then this is a red alert situation.

Now this is for a single CPU – if you have a load of 3.00 and a quad core CPU, this is okay.

You have, in the traffic analogy, four lanes of traffic, of which 3 are being used to capacity.

So we have a fourth lane free and it's as if we're at 75% utilization on a single CPU.

Back to our example. Is it CPU?

The Application Server CPU utilization, on average, was about 10% and on the database server, about 36%.

So that is probably not the cause.

Next on the list is memory.

One way to tell if memory is the limiting factor is actually to look at disk utilization.

If there is not enough RAM in the box, there will be swapping and then performance goes out the window and scalability goes with.

That is of course, the worst case. You can ask via `top` about how much swap is being used, but that's probably not the interesting value.

```
KiB Mem:  8167736 total,  6754408 used,  1413328 free,   172256 buffers
KiB Swap:  8378364 total,  1313972 used,  7064392 free.  2084336 cached Mem
```

This can be misleading though, because memory being “full” does not necessarily mean anything bad.

It means the resource is being used to its maximum potential, yes, but there is no benefit to keeping a block of memory open for no reason.

Also, memory is not like the CPU; if there's nothing for the CPU to do, it will just idle (low power state).

Memory won't "forget" data if it doesn't happen to be needed right now - data will hang around in memory until there is a reason to move or change it.

So freaking out about memory appearing as full is kind of like getting all in a knot about how "System Idle Process" is hammering the CPU...

You can also ask about page faults, with the command `ps -eo minflt,majflt,cmd`.

Major page faults: had to fetch from disk.

Minor page faults: had to copy a page from another process.

The output of this is too big even for the notes.

This is lifetime data.

What you really want is to ask Linux for a report on swapping:

```
jz@Loki:~$ vmstat 5
```

```
procs -----memory----- ---swap-- -----io----- -system-- -----cpu-----
 r  b   swpd   free   buff  cache   si   so    bi    bo    in   cs  us  sy  id  wa  st
 1  0 1313972 1414600 172232 2084296    0    0     3    39     1     1 27   1 72   0   0
 0  0 1313972 1414476 172232 2084296    0    0     0    21   359   735 19   0 80   0   0
 0  0 1313972 1414656 172236 2084228    0    0     0   102   388   758 22   0 78   0   0
 4  0 1313972 1414592 172240 2084292    0    0     0    16   501   847 33   0 67   0   0
 0  0 1313972 1412028 172240 2084296    0    0     0     0   459   814 29   0 71   0   0
```

# Swapping Report with Actual Swapping

procs			swpd	free	memory			swap			io		system		cpu	
r	b	w			buff	cache	si	so	bi	bo	in		cs	us	sy	id
.	.	.														
1	0	0	13344	1444	1308	19692	0	168	129	42	1505		713	20	11	69
1	0	0	13856	1640	1308	18524	64	516	379	129	4341		646	24	34	42
3	0	0	13856	1084	1308	18316	56	64	14	0	320		1022	84	9	8

Looking at disk might seem slightly redundant if memory is not the limiting factor.

After all, if the data were in memory it would be unnecessary to go to disk in the first place.

Still, sometimes we can take a look at the disk and see if that is our bottleneck.

# Looking at Disk Usage

```
jz@Loki:~$ iostat -dx /dev/sda 5
Linux 3.13.0-24-generic (Loki) 16-02-13 _x86_64_ (4 CPU)

Device:            rrqm/s    wrqm/s      r/s      w/s    rkB/s    wkB/s avgrq-sz avgqu-sz   await r_await w_await  svctm  %util
sda                 0.24      2.78    0.45    2.40    11.60    154.98   116.91     0.17   61.07  11.57   70.27   4.70   1.34
```

It's that last column, %util that tells us what we want to know.

We can ask about the network with `nload`.

You get a nice little graph if there is anything to see.

But you'll get the summary, at least:

```
Curr: 3.32 kBit/s  
Avg: 2.95 kBit/s  
Min: 1.02 kBit/s  
Max: 12.60 kBit/s  
Ttl: 39.76 GByte
```

he book contains the full story, which is maybe interesting to you if you wanted to dig into the specifics about Oracle 10g and SQL query syntax.

I speculate that you do not care about the details, but 96.4% of the total database call time was attributed to database CPU

Sure enough, the “top 5” queries were taking up a huge amount of time and they all look something like:

```
SELECT documentId, classId, dataGroupId, consistencyId FROM object
```

Why does performance of this stink?

We're doing a lot of reads from the database.

The reads themselves don't necessarily go to disk (cache/buffers/etc may save us here) but we're still doing a lot of reads of data.

To speed this up, what we need is to add an additional index for each of these tables.

This is one of the strategies we've talked about before – “be prepared”.

# The Impact of the Index
