

# Lecture 8 — Of Asgard and Hel

Jeff Zarnett

`jzarnett@uwaterloo.ca`

Department of Electrical and Computer Engineering  
University of Waterloo

December 28, 2016

Everything came into creation in the gap between fire and ice, and the World Tree (Yggdrasil) connects the nine worlds.

Asgard is the home of the Æsir, the Norse gods.

Helheim, or simply Hel, is the underworld where the dead go upon their death.

In Hel or Asgard (it's not clear), there is Valhalla, hall of the honoured dead.

# Carry We, Who Die In Battle...

Those who die in battle and are judged worthy will be carried to Valhalla by the Valkyries.

There they will reside until they are called upon to aid in Odin's fight with the wolf Fenrir in Ragnarök.

humans live in the “middle realm”, Midgård, surrounded by the serpent Jormungand, who will fight against Thor in Ragnarök.

Thor will kill the serpent, but the serpent's poison will also finish off Thor.

# Across the Rainbow Bridge, To Valhalla...

We're going to examine some very useful tools for programming called Valgrind and Helgrind (also Cachegrind).

Where do they take their names from? Valgrind is the gateway to Valhalla; a gate that only the worthy can pass.

Helgrind is the gateway to, well, Hel.

Sadly, the authors of Cachegrind failed to choose a name that corresponds to a location in the nine worlds of Norse mythology.

But all of these are analysis tools for your C and C++ programs.

They are absolute murder on performance, but they are wonderful for finding errors in your program.

To use them, start the tool of your choice and instruct it to invoke your program.

The target program then runs under the “supervision” of the tool.

Remember to enable debugging symbols in your compile.

Valgrind is the base name of the project and by default what it's going to do is run the memcheck tool.

The purpose of memcheck is to look into all memory reads, writes, and to intercept and analyze every call to `malloc/free` and `new/delete`.

Memcheck can find problems like:

- Accessing uninitialized memory
- Reading off the end of an array
- Memory leaks
- Incorrect freeing of memory
- Incorrect use of C standard functions like `memcpy`
- Using memory after it's been freed.
- Asking for an invalid number of bytes in an allocation

```
jz@Loki:~/ece254$ valgrind ./search
==8476== Memcheck, a memory error detector

# No, It's Because I'm Awesome

Okay, everything going perfectly is unlikely in anything other than a small program.

The exam question I used this on is something like 62 lines (including blanks).

So it's a trivial program. But I'll sabotage it a bit so we get a more interesting result.

Suppose I delete from the code two of the `free()` calls.

# Hence the word... Sabotage

```
jz@Loki:~/ece254$ valgrind ./search

# Send the Plumbers to the Watergate

Take the program's suggestion to use the `-leak-check=full`.

You get a bit more detail about where you made the mistake.

In the example below, lines 49 and 24 in the file `search.c` are the locations of the `malloc` calls that lack a matching call to `free`.

It can't tell you where the call to `free` should go, only where the memory that isn't freed was allocated.

```
==8553== 16 bytes in 4 blocks are definitely lost in loss record 1 of 2
==8553==    at 0x4C2AB80: malloc (in /usr/lib/valgrind/vgpreload_memcheck-amd64-linux.so)
==8553==    by 0x40084D: search (search.c:49)
==8553==    by 0x4E3F181: start_thread (pthread_create.c:312)
==8553==    by 0x514F47C: clone (clone.S:111)
==8553==
==8553== 48 bytes in 4 blocks are definitely lost in loss record 2 of 2
==8553==    at 0x4C2AB80: malloc (in /usr/lib/valgrind/vgpreload_memcheck-amd64-linux.so)
==8553==    by 0x40074E: main (search.c:24)
```

But it's also important to learn what to ignore.

I decided to deploy Valgrind on the solution to the producer-consumer problem from ECE 254 and I ended up with a result that says:

```
==8734==      possibly lost: 544 bytes in 2 blocks
```

Hmm. Let's dig into that with the `-leak-check=full` option:

```
==8734== 272 bytes in 1 blocks are possibly lost in loss record 1 of 2
==8734==    at 0x4C2CC70: calloc (in /usr/lib/valgrind/vgpreload_memcheck-amd64-linux.so)
==8734==    by 0x4012E54: _dl_allocate_tls (dl-tls.c:296)
==8734==    by 0x4E3FDA0: pthread_create@@GLIBC_2.2.5 (allocatestack.c:589)
==8734==    by 0x400A57: main (mutex.c:64)
```

Looking in the file, at that line, we see a call to `pthread_create` and this is therefore probably nothing we need to do anything about.

- **Definitely lost**
- **Indirectly lost**
- **Possibly lost**
- **Still reachable**
- **Suppressed**

The purpose of Helgrind is to detect errors in the use of POSIX pthreads.

In a way, Helgrind is a pretty neat tool for improving performance, even though it doesn't actually directly speed anything up.

When we take single-threaded program and split it off into a multithreaded program, we may introduce a lot of errors.

Humans are not very good at parallel thinking; we are very much sequential.

But a program that is fast and wrong is probably less useful than one that is slow and correct.

But can we make it faster and still have it be correct?

That's the goal of Helgrind: determine where, if anywhere, there are concurrency problems.

It can't prove that your program is correct (if only) but it can at least catch some of the common problems you might introduce when writing a parallel program.

Helgrind will categories errors into three basic categories:

- 1 Misuses of the pthreads API
- 2 Lock ordering problems
- 3 Data races

The first category does not require much explanation:

- Unlocking a mutex that is unlocked
- Deallocation of memory with a locked mutex in it
- Thread exit while holding a locked lock

... and many more.

```
Thread #1 unlocked a not-locked lock at 0x7FEFFFA90
  at 0x4C2408D: pthread_mutex_unlock (hg_intercepts.c:492)
  by 0x40073A: nearly_main (tc09_bad_unlock.c:27)
  by 0x40079B: main (tc09_bad_unlock.c:50)
Lock at 0x7FEFFFA90 was first observed
  at 0x4C25D01: pthread_mutex_init (hg_intercepts.c:326)
  by 0x40071F: nearly_main (tc09_bad_unlock.c:23)
  by 0x40079B: main (tc09_bad_unlock.c:50)
```

The second category of errors should be familiar to you:

## Thread P

1. wait( a )
2. wait( b )
3. [critical section]
4. signal( a )
5. signal( b )

## Thread Q

1. wait( b )
2. wait( a )
3. [critical section]
4. signal( b )
5. signal( a )

Potential Deadlock!

Risk of deadlock: thread P holds mutex a and thread Q holds mutex b.

Each waits for the mutex that the other one has.

The example is slightly silly, of course, because it's super easy to see.

There will not necessarily be an obvious (alphabetical) order.

Helgrind builds a directed graph of lock acquisitions, so that when a thread acquires a lock, the graph is checked to see if a cycle exists.

It will report as an error the initial order (the first order seen is the one viewed as “correct”) and the the “incorrect” order that is the source of the potential problem.

Really, though, all that matters is consistency.

Thread #1: lock order "0x7FF0006D0 before 0x7FF0006A0" violated

Observed (incorrect) order is: acquisition of lock at 0x7FF0006A0  
at 0x4C2BC62: pthread\_mutex\_lock (hg\_intercepts.c:494)  
by 0x400825: main (tc13\_laog1.c:23)

followed by a later acquisition of lock at 0x7FF0006D0  
at 0x4C2BC62: pthread\_mutex\_lock (hg\_intercepts.c:494)  
by 0x400853: main (tc13\_laog1.c:24)

Required order was established by acquisition of lock at 0x7FF0006D0  
at 0x4C2BC62: pthread\_mutex\_lock (hg\_intercepts.c:494)  
by 0x40076D: main (tc13\_laog1.c:17)

followed by a later acquisition of lock at 0x7FF0006A0  
at 0x4C2BC62: pthread\_mutex\_lock (hg\_intercepts.c:494)  
by 0x40079B: main (tc13\_laog1.c:18)

The third category we have discussed already.

Recall the earlier definition of a race condition.

Helgrind looks for when two threads access the same memory location without using locks.

```

jz@Loki:~/ece459$ valgrind --tool=helgrind ./datarace

==10389==    by 0x515547C: clone (clone.S:111)
```

Note that we get two stack traces here: we have a read after write, and a write after write.

Why?

Because the operation in question is `var++` which necessitates fetching the current value of `var` (reading it) and incrementing it (then writing it back).

It examines the use of the standard threading primitives - lock, unlock, signal/post, wait...

Anything that implies there might be an ordering between events is taken and added to a directed acyclic graph that represents these dependencies.

If memory is accessed from two different threads and there is no path through this directed acyclic graph that indicates an ordering, then a race is reported.

Although obviously at least one of these accesses must be a write.

You can ask Helgrind to try to tell you about variable names (if it can) with the command line option `-read-var-info=yes`.

```
==10454== Location 0x60104c is 0 bytes inside global var "var"  
==10454== declared at datarace.c:3
```

The authors of Helgrind assume that if it tells you where the problem is, you will figure out what variables are affected and how to properly prevent data races.

You might find this frustrating.

Helgrind + OpenMP + Linux can cause the occasional problem in GCC 4.2 and 4.3; the “futex” system call in Linux is not visible to Helgrind.

You can rebuild GCC with the option `-disable-linux-futex` and that will hopefully work it out.

This is much more performance oriented than the other two tools.

It runs simulation of how your program interacts with cache and evaluates how your program does on branch prediction.

As we discussed earlier, cache misses and branch mispredicts have a huge impact on performance.

Recall that a miss from the fastest cache results in a small penalty (10 cycles).

A miss that requires going to memory requires about 200 cycles.

A mispredicted branch costs somewhere between 10-30 cycles.

Cachegrind reports data about:

- The First Level Instruction Cache (I1) [L1 Instruction Cache]
- The First Level Data Cache (D1) [L1 Data Cache]
- The Last Level Cache (LL) [L3 Cache].

Unlike normal Valgrind operation, you probably want to turn optimizations on.

```

```

Interesting results: our data and instruction miss rates went down marginally but the branch mispredict rates went up! W

ell sort of - there were fewer branches and thus fewer we got wrong as well as fewer we got right.

So the total cycles lost to mispredicts went down.

Is this an overall win for the code? Yes.

In some cases it's not so clear cut, and we could do a small calculation.

If we just take a look at the LL misses (4 544 vs 4 487) and assume they take 200 cycles, and the branch miss penalty is 200 cycles, it went from 908 800 wasted cycles to 897 400; a decrease of 11 400 cycles.

Repeat for each of the measures and sum them up to determine if things got better overall and by how much.

Cachegrind also produces a more detailed output file, titled `cachegrind.out.<pid>` (the PID in the example is 16618).

This file is not especially human-readable, but we can ask the associated tool `cg_annotate` to break it down for us.

The output is way too big for slides.

Cachegrind is very... verbose... and it can be very hard to come up with useful changes based on what you see...

Assuming your eyes don't glaze over when you see the numbers.

Probably the biggest performance impact is last level cache misses (those appear as DLmr or DLmw).

You might also try to look at the Bcm and Bim (branch mispredictions) to see if you can give some better hints.

Of course, to learn more about how Cachegrind, the manual is worth reading.

Not that anybody reads manuals anymore...

Just give it a shot, when you get stuck, google the problem, click the first stack overflow link result...
