## Lock Convoys

Too much CPU time handling context switches!

# Weird Side Effects of Lock Convoys

Threads acquire the lock frequently and they are running for very short periods of time before blocking.

Other, unrelated threads of the same priority get to run for an unusually large percentage of the (wall-clock) time.

You might think another process is the real offender.

In Windows Vista and later versions, the problem is solved because locks are unfair.

Windows XP: if a lock  $\ell$  is unlocked by  $A$  and there is a thread  $B$  waiting, then  $B$  gets it.

$B$  is no longer blocked, and  $B$  already owns the lock when it wakes up.

The lock can never be “stolen”; hence “fair”.

But! There is a period of time where the lock is held by  $B$ , but  $B$  is not running.

If thread  $C$  starts to run and requests  $\ell$ , it gets stuck, and we pay more context switch costs.

# How Unfairness Mitigates Lock Convoys

Thread  $A$  releases lock  $\ell$ .  $B$  wants it.

Let's be unfair.  $B$  doesn't get it.

Say  $B$  runs next. Then it requests  $\ell$  and gets it.

What if  $C$  runs next instead? Then it computes.

- If  $C$  wants  $\ell$ , it gets it; maybe releases before switchout.
- If  $C$  didn't need  $\ell$ , nothing to see here.

# Diagnosing Lock Convoys

waiting:

$t_1, t_2, t_3$

but no owner!

Changing the locks to be unfair does risk starvation.

Windows does give a thread priority boost, temporarily, after it gets unblocked, to see to it that the unblocked thread does actually get a chance to run.

Although it can be nice to be able to give away such a problem to the OS developers, we might have to solve it for ourselves.

Options:

- Sleep
- Share
- Cache
- Trylock

We could make the threads that are NOT in the lock convoy call a `sleep()` system call fairly regularly to give other threads a chance to run.

This solution is lame, though, because we're changing the threads that are not the offenders.

It just band-aids the situation so the convoy does not totally trash performance.

Still, we are doing a lot of thread switches, which themselves are expensive as outlined above.

Young toekans sharing food

The next idea is sharing: can we use a reader-writer lock to allow much more concurrency than we would get if everything used exclusive locking?

If there will be a lot of writes then there's limited benefit to this speedup, but if reads are the majority of operations then it is worth doing.

We can also try to find a way to break a critical section up into two or more smaller ones, if that can be done correctly!

# Nevermind, I wanted something else...

The next idea has to do with changing when (and how) you need the data.

Shrink the critical section to just pull a copy of the shared data and operate on the shared data.

But you saw the earlier discussion about critical section sizes, right? So you did that already...?

The last solution suggested is to use try-lock primitives:

---

```
int retries = 0;
while(pthread_mutex_trylock( &lock ) != 0 ) { /* 0 indicates lock acquired */
    if ( retries < SPIN_LIMIT ) {
        retries++;
        sleep(0);
        continue;
    }
    pthread_mutex_lock( &lock );
    break;
}
```

---

If we reach the limit then we just give up and enter the queue!

It looks like polling for the critical section.

The limit on the number of tries helps in case the critical section belongs to a low priority thread and we need the current thread to be blocked.

Under this scheme, if  $A$  is going to release the critical section,  $B$  does not immediately become the owner.

$A$  may keep running and  $A$  might even get the critical section again before  $B$  tries again to acquire the lock (and may succeed).

Even if the spin limit is as low as 2, this means two threads can recover from contention without creating a convoy

You've been... THUNDERSTRUCK!

Credit: public domain, Famous Players, 1925

# You've been... THUNDERSTRUCK!

The lock convoy has some similarities with a different problem called the **thundering herd problem**.

In the thundering herd problem, some condition is fulfilled (e.g., broadcast on a condition variable) and it triggers a large number of threads to wake up.

It is likely they can't all proceed, so some will get blocked and then awoken again all at once in the future.

In this case it would be better to wake up one thread at a time instead of all of them.

Credit: public domain, John Collier, *Sleeping Beauty*, 1929

Beware! Waking up one thread at a time only works when threads are identical.

Otherwise, you're better off waking all the threads just in case, to avoid correctness issues.

Atomics are a lower-overhead alternative to locks as long as you're doing suitable operations.

Sometimes: just want that operations are indivisible.

Key idea: an **atomic operation** is indivisible.

Other threads see state before or after the operation; nothing in between.

Use the default `std::memory_order`.  
(= sequential consistency)

Don't use relaxed atomics unless you're an expert!

- `memory_order_acquire`
- `memory_order_release`
- `memory_order_acq_rel`
- `memory_order_consume`
- `memory_order_relaxed`
- `memory_order_seq_cst`

Really, don't use C++ relaxed atomics!

An *atomic operation* is indivisible.

Other threads see state before or after the operation, nothing in between.

Represents a boolean flag.

---

```
#include <atomic>
```

```
atomic_flag f = ATOMIC_FLAG_INIT;
```

---

Can clear, and can test-and-set:

---

```
#include <atomic>

atomic_flag f = ATOMIC_FLAG_INIT;
int foo() {
    f.clear();
    if (f.test_and_set()) {
        // was true
    }
}
```

---

test\_and\_set: atomically sets to true,  
returns previous value.

No assignment (=) operator.

Although I guess in C++ you could define one if you wanted.

This is kind of a dangerous thing about C++.

If in C you see a line of code like `z = x + y;` you can have a pretty good idea about what it does and you can infer that there's some sort of natural meaning to the `+` operator there, like addition or concatenation.

In C++, however, this same line of code tells you nothing unless you know...

- (1) the type of `x`,
- (2) the type of `y`, and
- (3) how the `+` operator is defined on those two operands *in that order*.

But I'm digressing.

Declaring them:

---

```
#include <atomic>
```

```
atomic<int> x;
```

---

Library's implementation:  
on small types, lock-free operations;  
on large types, mutexes.

Kinds of operations:

- reads
- writes
- read-modify-write (RMW)

C++ has syntax to make these all transparent:

---

```
#include <atomic>
#include <iostream>

std::atomic<int> ai;
int i;

int main() {
    ai = 4;
    i = ai;
    ai = i;
    std::cout << i;
}
```

---

Can also use `i = ai.load()` and `ai.store(i)`.

Consider `ai++`.

This is equivalent to (under lock):

```
tmp = ai.read(); tmp++; ai.write(tmp);
```

Hardware can do that atomically, and faster.

Other RMWs: `+-`, `&=`, etc, compare-and-swap

Suppose we'd like to operate in a world in which there are no locks.

Research has gone into the idea of lock-free data structures.

If you have a map and it will be shared between threads, the normal thing would be to protect access to the map with a mutex (lock).

But what if the data structure was written in such a way that we didn't have to do that?

That would be a lock-free data structure.

Often, normal locking and unlocking behaviour is sufficient.

We likely want to use it when we need to guarantee that progress is made.

Or: when we really can't use locks (e.g., signal handler), or where a thread dying while holding a lock results in the whole system hanging.

A non-blocking data structure is one where none of the operations can result in being blocked.

In a language like Java there might be some concurrency-controlled data structures in which locking and unlocking is handled for you, but those can still be blocking.

Lock-free data structures are always inherently non-blocking.

A spin lock or busy-waiting approach is not lock free, because if the thread holding the lock is suspended then everyone else is stuck!

A lock-free data structure doesn't use any locks (duh) but there's also some implication that this is also thread-safe.

You can't make all your data structures lock-free ones by just deleting all the mutex code (sorry).

Lock free also doesn't mean it's a free-for-all; there can be restrictions.

For example, a queue that allows one thread to append to the end while another removes from the front, but not 2 removals at the same time.

The actual definition of lock-free is more formal.

If any thread performing an operation gets suspended during the operation, then other threads accessing the data structure are still able to complete their tasks.

This is distinct from the idea of waiting, though; an operation might still have to wait its turn or might get restarted.

You might need wait-free data structures.

This does not mean that nothing ever has to wait!

It does mean that each thread trying to perform some operation will complete it within a bounded number of steps regardless of what any other threads do.

This means that a compare-and-swap routine with infinite retries is not wait free, because a very unlucky thread could potentially take infinite tries...

The wait free data structures tend to be very complicated...

# Example Lock-Free Algorithm

---

```
void stack_push(stack* s, node* n) {  
    node* head;  
    do  
    {  
        head = s->head;  
        n->next = head;  
    }  
    while ( !atomic_compare_exchange(s->head, head, n) );  
}
```

---

# Example Wait-Free Algorithm

---

```
void increment_reference_counter(rc_base* obj) {  
    atomic_increment(obj->rc);  
}  
  
void decrement_reference_counter(rc_base* obj) {  
    if (0 == atomic_decrement(obj->rc))  
        delete obj;  
}
```

---

# To Lock Free, or Not to Lock Free

Are lock-free programming techniques somehow better for performance?  
Maybe!

Lock free algorithms are about ensuring there is forward progress in the system and not really specifically about speed.

A particular algorithm implementation might be faster under lock-free algorithms.

But often they are not. In fact, the lock free algorithms could be slower, in which case you use them because you must, not because it is particularly speedy.
