Asynchronous I/O on linux

or: **Welcome** to **hell**.

(mirrored at compgeom.com/~piyush/teach/4531_06/project/hell.html)

"Asynchronous I/O, for example, is often infuriating."
— Robert Love. *Linux System Programming, 2nd ed,* page 215.

Consider some I/O:

```
fd = open (...);
read (...);
close (fd);
```

Not very performant—under what conditions do we lose out?

So far: can use threads to mitigate latency.
What are the disadvantages?

So far: can use threads to mitigate latency.
What are the disadvantages?

- race conditions
- overhead/max # of thread limitations

Asynchronous/nonblocking I/O.

```
fd = open (..., O_NONBLOCK);
read (...); // returns instantly!
close (fd);
```

...

(credit: Yskyflyer, Wikimedia Commons)

Doesn't work on files—they're always ready. Only e.g. sockets.

How do you know when I/O is ready to be queried?

How do you know when I/O is ready to be queried?

- polling (`select`, `poll`, `epoll`)
- interrupts (signals)

Key idea: give `epoll` a bunch of file descriptors;
    wait for events to happen.

Steps:

1 create an instance (`epoll_create1`);

2 populate it with file descriptors (`epoll_ctl`);

3 wait for events (`epoll_wait`).

```
int epfd = epoll_create1(0);
```

`efpd` doesn't represent any files; use it to talk to `epoll`.

0 represents the flags (only flag: EPOLL_CLOEXEC).

To add `fd` to the set of descriptors watched by `epfd`:

```
struct epoll_event event;
int ret;
event.data.fd = fd;
event.events = EPOLLIN | EPOLLOUT;
ret = epoll_ctl(epfd, EPOLL_CTL_ADD, fd, &event);
```

Can also modify and delete descriptors from `epfd`.

Now we're ready to wait for events on any file descriptor in `epfd`.

```
#define MAX_EVENTS 64

struct epoll_event events[MAX_EVENTS];
int nr_events;

nr_events = epoll_wait(epfd, events, MAX_EVENTS, -1);
```

-1: wait potentially forever; otherwise, milliseconds to wait.

Upon return from `epoll_wait`, we have `nr_events` events ready.

Default `epoll` behaviour is level-triggered:
   return whenever data is ready.

Can also specify (via `epoll_ctl`) edge-triggered behaviour:
   return whenever there is a change in readiness.

POSIX standard defines aio calls.

These work for disk as well as sockets.

Key idea: you specify the action to occur when I/O is ready:

- nothing;
- start a new thread;
- raise a signal

Submit the requests using e.g. `aio_read` and `aio_write`.

Can wait for I/O to happen using `aio_suspend`.

Similar idea to `epoll`:

- build up a set of descriptors;
- invoke the transfers and wait for them to finish;
- see how things went.

Here's a simple cURL program that we can look over:

```c
#include <stdio.h>
#include <curl/curl.h>

int main( int argc, char** argv ) {
  CURL *curl;
  CURLcode res;

  curl_global_init(CURL_GLOBAL_DEFAULT);

  curl = curl_easy_init();
  if( curl ) {
    curl_easy_setopt(curl, CURLOPT_URL, "https://example.com/" );
    res = curl_easy_perform( curl );

    if( res != CURLE_OK ) {
        fprintf(stderr, "curl_easy_perform() failed: %s\n", curl_easy_strerror(
            res));
    }
    curl_easy_cleanup(curl);
  }

  curl_global_cleanup();
  return 0;
}
```
curl_multi: work with multiple resources at once.

1. To use `curl_multi`, first create the individual requests
   (`curl_easy_init`).
   (Set options as needed on each handle).

2. Then, combine them with:

   - `curl_multi_init();`
   - `curl_multi_add_handle().`

Start reqs: `curl_multi_perform( CURLM* cm, int* still_running )`

The second parameter is updated with the number of still-in-progress requests.

Meantime, we can do other things!

Suppose we've run out of things to do and nothing is ready yet. Wait!

```
curl_multi_wait ( CURLM *multi_handle , struct curl_waitfd extra_fds [] ,
unsigned int extra_nfds , int timeout_ms , int *numfds )
```

This function will block the current thread until something happens.

Choose how long to wait and see how many events occurred.

While we are asleep or doing other things, callbacks still happen.

The status of the cURL easy handle is updated.

`curl_multi_info_read` will tell you.

```
msg = curl_multi_info_read(multi_handle, &msgs_left);
```

---

and also how many messages are left.

`msg->msg` can be CURLMSG_DONE or an error;
`msg->easy_handle` tells you who is done.

Some gotchas (thanks Desiye Collier):

- Checking `msg->msg == CURLMSG_DONE` is not sufficient to ensure that a curl request actually happened. You also need to check `data.result`.
- (A1 hint:) To reset an individual handle in the `multi_handle`, you need to "replace" it. But you shouldn't use `curl_easy_init()`. In fact, you don't need a new handle at all.

Call `curl_multi_cleanup` on the multi handle.

Then, call `curl_easy_cleanup` on each easy handle.

If you replace `curl_easy_init` by `curl_global_init`,
then call `curl_global_cleanup` also.

The long example is too big for the slides.

We'll have to take look at it in the notes!

- Blocking I/O; 1 process per request.
- Blocking I/O; 1 thread per request.
- Asynchronous I/O, pool of threads,
  callbacks,
  each thread handles multiple connections.
- Nonblocking I/O, pool of threads,
  multiplexed with select/poll, event-driven,
  each thread handles multiple connections.

Old Apache model:

- Main thread waits for connections.
- Upon connect, forks off a new process,
  which completely handles the connection.
- Each I/O request is blocking:
  e.g. reads wait until more data arrives.

Advantage:

- "Simple to understand and easy to program."

Disadvantage:

- High overhead from starting 1000s of processes.
  (can somewhat mitigate with process pool).

Can handle ~10 000 processes, but doesn't generally scale.

We know that threads are more lightweight than processes.

Same as 1 process per request, but less overhead.

I/O is the same—still blocking.

Advantage:

- Still simple to understand and easy to program.

Disadvantages:

- Overhead still piles up, although less than processes.
- New complication: race conditions on shared data.

In 2006, perf benefits of asynchronous I/O on lighttpd[1]:

version		fetches/sec	bytes/sec	CPU idle
1.4.13	sendfile	36.45	3.73e+06	16.43%
1.5.0	sendfile	40.51	4.14e+06	12.77%
1.5.0	linux-aio-sendfile	72.70	7.44e+06	46.11%

(Workload: 2×7200 RPM in RAID1, 1GB RAM,
    transferring 10GBytes on a 100MBit network).

---

[1] http://blog.lighttpd.net/articles/2006/11/12/lighty-1-5-0-and-linux-aio/

Basic workflow:

1 enqueue a request;

2 ... do something else;

3 (if needed) periodically check whether request is done; and

4 read the return value.

```
#include <aio.h>

int main() {
    // so far, just like normal
    int file = open("blah.txt", O_RDONLY, 0);

    // create buffer and control block
    char* buffer = new char[SIZE_TO_READ];
    aiocb cb;

    memset(&cb, 0, sizeof(aiocb));
    cb.aio_nbytes = SIZE_TO_READ;
    cb.aio_fildes = file;
    cb.aio_offset = 0;
    cb.aio_buf = buffer;
```

```
// enqueue the read
if (aio_read(&cb) == -1) { /* error handling */ }

do {
  // ... do something else ...
while (aio_error(&cb) == EINPROGRESS); // poll

// inspect the return value
int numBytes = aio_return(&cb);
if (numBytes == -1) { /* error handling */ }

// clean up
delete[] buffer;
close(file);
```

Each thread handles multiple connections.

When a thread is ready, it uses select/poll to find work.

- perhaps it needs to read from disk into a mmap'd tempfile;
- perhaps it needs to copy the tempfile to the network.

In either case, the thread does work and updates the request state.
